MR-FQ: A Fair Scheduling Algorithm for Wireless Networks with Variable Transmission Rates

You-Chiun Wang, Yu-Chee Tseng, and Wen-Tsuen Chen

Abstract—Wireless networks are characterized by bursty and location-dependent errors. Although many fair scheduling algorithms have been proposed to address these issues, most of them assume a simple two-state channel model, where a channel can be either good or bad. In fact, the situation is not so pessimistic because different modulation techniques can be used to adapt to different channel conditions. Multi-rate transmission is a common technique for wireless networks nowadays. This leads to a dilemma: should fairness be built based on the amount of time that a user utilizes the medium or the amount of services that a user receives? In this work, we propose a Multi-rate wireless Fair Queueing (MR-FQ) algorithm that allows a flow to transmit at different rates according to its channel condition and lagging degree. MR-FQ takes both time and service fairness into account. We demonstrate that MR-FQ can guarantee fairness and bounded delays for packet flows by mathematical modeling and analyses. Besides, simulation results show that MR-FQ can also increase the overall system throughput compared to other scheduling methods.

Index Terms—communication network, fair scheduling, multi-rate communication, quality of service (QoS), wireless network.

1 INTRODUCTION

We have seen huge growth of wireless data services over the recent years. The increasing importance of real-time applications further demands provision of QoS and fair channel access among multiple packet flows over a shared, bandwidth-limited, error-prone wireless channel. In wireline networks, many fair scheduling algorithms [1]–[6] have been proposed to bound delays of packet transmission. However, wireless channels are characterized by the following features that distinguish themselves from wireline networks: 1) more serious bursty errors, 2) location-dependent errors, and 3) multi-rate communication capability. Bursty errors may break continuous services of a flow, while location-dependent errors may allow error-free flows to receive more services than they deserve, thus violating the fairness and bounded-delay requirements. A wireless channel may provide different transmission rates to different terminals depending on channel qualities (e.g., IEEE 802.11a supports 16 rates, while 802.11b supports 4 rates). Due to these reasons, existing wireline solutions may not be suitable for the wireless networks [7], [8].

Many fair scheduling algorithms have been proposed to address the features 1) and 2) of wireless networks. In Idealized Wireless Fair Queueing (IWQ) [9], each packet is associated with a finish tag computed by the principles of Weight Fair Queueing (WFQ) [2], and the scheduler always serves the error-free packet with the smallest finish tag. When a flow suffers from errors, all its packets keep their original tags. After the flow exits from errors, its packets are likely to have smaller finish tags. So the scheduler will serve this flow and thus compensates its lost services. In Channel-condition Independent Fair Queueing (CIF-Q) [10], fairness is achieved by transferring the services allocated to error flows to those error-free flows. Then compensation services are dispatched to the former proportional to their weights. In Server Based Fairness Approach (SBFA) [11], a fraction of bandwidth is reserved particularly to compensate those error flows. A number of virtual servers called Long Term Fairness Servers (LTFS) are created for those flows that experienced errors. Later on, the reserved bandwidth is used to compensate these flows recorded in LTFS. Wireless Fair Service (WFS) [12] addresses the delay-weight coupling problem, and alleviates the problem by assigning each flow with a rate weight and a delay weight. A flow is drained into the scheduler according to its rate weight, but served according to its delay weight. In Traffic-Dependent wireless Fair Queueing (TD-FQ) [13], flows are separated into real-time (RT) flows and non-real-time (NRT) flows. The scheduler gives higher priorities to real-time flows to reduce their queueing delays, while still maintains fairness and bounded delays for all flows.

Unfortunately, the feature 3) of wireless networks has not been well addressed in the area of fair queuing. Most works assume that a wireless channel is either in a good (error-free) state or a bad (error) state. Transmissions in a good state will succeed, but completely fail in a bad state. In fact, the situation is not so pessimistic because different modulation techniques can be used to adapt to different channel conditions. The PHY of IEEE 802.11a/b are well-known examples, which can provide multi-rate transmission capabilities [14], [15]. A simpler modulation (and thus a higher data rate) can be used when the signal-to-noise ratio (SNR) is sufficiently high, while a more complicated modulation (and thus a lower rate) can still be used under a bad channel [16]. Adopting multi-rate transmissions poses several challenges to fair queuing. First, there is a mismatch between the amount of service that a client receives and the amount of time that a server actually serves a client. To transmit the same amount of data, a client using a lower rate will take longer time than one using a higher rate. So the concept of virtual time (such as finish tags) may need to be redefined. Second, when a flow that
suffered from a bad channel exits from error, it may take a different amount of time for the system to compensate the flow depending on its channel condition, thus making the design of compensation difficult. Third, the overall system performance may be degraded if there are too many low-rate flows.

In this work, we consider the fair scheduling problem in a wireless network with a TDMA MAC protocol and multi-rate communication capability. We propose a new algorithm called Multi-rate wireless Fair Queueing (MR-FQ). MR-FQ can adjust a flow’s transmission rate according to its channel condition and lagging degree. A flow is allowed to transmit at a lower rate to alleviate its lags only if it is lagging up to a certain degree. More specifically, the more serious a flow is lagging, the lower rate the flow is allowed to use. Such differentiation can take care of both fairness and system performance. Lower-rate flows thus will not prolong other flows’ delays. Besides, MR-FQ follows the idea in [13] by separating real-time flows from NRT ones and compensates real-time lagging flows with higher priorities than NRT lagging flows to reduce the former’s delays. However, such a special treatment does not starve NRT flows. Thus, MR-FQ can satisfy the delay-sensitive property of RT applications, while still maintain fairness and bounded delays for all flows.

Several works have tried to differentiate flows’ error conditions by adjusting their weights, but they still do not address the multi-rate feature. Effort-Limited Fair (ELF) [17] suggests adjusting each flow’s weight in response to the error rate of that flow, up to a maximum defined by that flow’s power factor. In Channel State independent Wireless Fair Queuing (CS-WFQ) [18], each flow i is associated with a fair share φi and a time-varying factor fi(t). The latter is used to adjust the former according to error rates. In Channel Adaptive Fair Queuing (CAFQ) [19], the weight of each flow i is also adjusted by a factor M(Φi)n, where M(Φi) reflects the channel states and 0 ≤ M(Φi) ≤ 1. The works in [20]–[23] address the multi-rate issue, but the focus is on assigning codes or adjusting transmission powers in CDMA networks.

The remainder of this paper is organized as follows: Section 2 presents our MR-FQ algorithm. In Section 3, we demonstrate the properties of MR-FQ (such as fairness and bounded delays) by mathematical modeling and analyses. Section 4 presents some simulation results to verify the effectiveness and properties of MR-FQ. Conclusions are drawn in Section 5.

2 The MR-FQ Algorithm

2.1 System Model

We consider a base station (BS) as in Fig. 1. Packets arriving at the BS are classified into RT traffic and NRT traffic and dispatched into different flow queues depending on their destination mobile stations. These traffic flows are sent to the MR-FQ packet scheduler, which is responsible for scheduling flows and transmitting the head-of-line (HOL) packet of the selected flow to the MAC and transmission (MT) module. The MT module can transmit at n rates C1, C2, \cdots, Cn, where C1 > C2 > \cdots > Cn. It also measures the current channel condition to each mobile station and determines the most appropriate rate to communicate with the station (several works [16], [24]–[26] have addressed the rate selection problem, but this is out of scope of this work). The information of the best rate is also reported to the scheduler for making a decision. For simplicity, we assume that the BS has immediate knowledge of the best rate for each station. Note that this also includes the worst case where the channel is too bad to be used, in which case we can regard the best rate to be zero.

2.2 Service Fairness vs. Time Fairness

With the emergence of multi-rate communication, the concept of fairness may be defined in two ways. One is service fairness, which means that the difference between services received by any two flows should be bounded, and the other is time fairness, which means that the difference between the amounts of transmission time of any two flows should be bounded. Formally, let wi be the weight of flow i, and Φi(t1, t2) and Φj(t1, t2) be the amount of services and the amount of time that flow i receives/utilizes during the time interval [t1, t2], respectively. Then for any two flows i and j, during any [t1, t2],

\[
\left| \frac{\Phi_i(t_1, t_2)}{w_i} - \frac{\Phi_j(t_1, t_2)}{w_j} \right| \leq \sigma_s, \quad (1)
\]

holds if service fairness is desired, and

\[
\left| \frac{\Phi_i^s(t_1, t_2)}{w_i} - \frac{\Phi_j^s(t_1, t_2)}{w_j} \right| \leq \sigma_t, \quad (2)
\]

holds if time fairness is desired, where \( \sigma_s \) and \( \sigma_t \) are small, non-negative numbers.

We observe that in a single-rate environment, Eq. (1) and Eq. (2) are equivalent. However, in a multi-rate environment, Eq. (1) and Eq. (2) may not be satisfied at the same time. If service fairness is desired, then flows using lower rates will occupy more of the medium time. On the contrary, if time fairness is desired, then flows using higher rates will transmit more data. The concept is illustrated in Fig. 2. Furthermore, when the rates used by stations exhibit higher variation, the tradeoff between service and time fairness is more significant (solid line in Fig. 2). When the variation is lower, the tradeoff is less significant (dashed line in Fig. 2). When the variation is 0, this degenerates to the single-rate case (thick line in Fig. 2).
2.3 Scheduling Policy

Fig. 2 leads to the following guidelines in the design of MR-FQ. First, the concept of virtual time is redefined based on the concept of time fairness. However, we differentiate flows according to their lagging degrees. A flow is allowed to use a lower transmission rate only if it is suffering from a higher lagging degree. In this way, we can take care of service fairness. So the system performance would not be hurt when there exist too many low-rate stations.

In MR-FQ, like traditional fair queueing works, each flow is assigned a weight \( w_i \) to represent the ideal fraction of bandwidth that the system commits to it. For each flow \( i \), we maintain a virtual time \( v_i \) to record the nominal services received by it, and a lagging index \( l_{ag} \) to record its credits/debts. The former is used to compete with other flows for services, while the latter is used to arrange compensation services. The actual normalized service received by flow \( i \) is \( v_i = v_i - l_{ag}/w_i \). Flow \( i \) is called leading if \( l_{ag} < 0 \), called lagging if \( l_{ag} > 0 \), and called satisfied if \( l_{ag} = 0 \). Further, depending on its queue content, a flow is called backlogged if its queue is nonempty, called non-backlogged if its queue is empty, and called active if it is backlogged or non-backlogged but leading. Note that MR-FQ only selects active flows to serve. When a non-backlogged but leading flow is chosen, its service will actually be transferred to another flow for compensation purpose. Besides, whenever a flow \( i \) transits from non-backlogged to backlogged, its virtual time \( v_i \) is set to \( \min\{v_i, \min_{j \in A}\{v_j\}\} \), where \( A \) is the set of all active flows.

Fig. 3 outlines the scheduling policy of MR-FQ. First, the active flow \( i \) with the smallest virtual time \( v_i \) is selected. If flow \( i \) is backlogged, the Rate Selection Scheme is called to compute the best rate \( r \) to transmit for flow \( i \). If the result is \( r \leq 0 \), that means either flow \( i \) has a bad channel condition or its current lagging degree does not allow it to transmit (refer to Section 2.3.1 for details). Otherwise, if flow \( i \) is non-leading, the HOL packet of flow \( i \) will be served. Then we update the virtual time of flow \( i \) as follows:

\[
v_i = v_i + \left( \frac{l_p}{w_i} \times \frac{C^i}{r} \right),
\]

where \( l_p \) is the length of the packet. Note that the ratio \( \frac{C^i}{r} \) is to reflect the concept of time fairness. The amount of increase in \( v_i \) is inverse to the transmission rate \( r \). So if a lower \( r \) is used, the less competitive flow \( i \) will be in the next round.

If flow \( i \) is over-served (i.e., leading), the Graceful Degradation Scheme is activated to check if flow \( i \) is still eligible for the service (refer to Section 2.3.2). In case that flow \( i \) has to give up its service due to an empty queue, a bad channel condition, or a rejection decision by the Graceful Degradation Scheme, the service is transferred to the Compensation Scheme to select another flow \( j \) to serve (refer to Section 2.3.3). If the scheme fails to select any flow, this service is just wasted. If the scheme still selects flow \( i \) to serve, then we send its HOL packet and update \( v_i \) according to Eq. (3). If another flow \( j \) (\( \neq i \)) is selected, flow \( j \)'s packet is sent and the values of \( v_i \), \( l_{ag} \), and \( l_{ag} \) are updated as follows:

\[
v_i = v_i + \frac{l_p}{w_i}, \quad l_{ag} = l_{ag} + l_p, \quad l_{ag} = l_{ag} - l_p.
\]

where \( p' \) is the packet being sent. Note that in this case we charge flow \( i \) by increasing its virtual time (i.e., Eq. (4)), but credit to \( l_{ag} \) of flow \( i \) (i.e., Eq. (5)) and debit to \( l_{ag} \) of flow \( j \) (i.e., Eq. (6)). Since flow \( i \) is not actually served, Eq. (4) is equivalent to Eq. (3) with \( r = C^i \).

Whenever the scheduler serves any flow \( i \), it has to check the queue size of flow \( i \). If flow \( i \)’s queue state changes to non-backlogged and it is still lagging, we distribute its credit to other flows that are in debt and reset its credit to zero. This is because the flow does not need the credit any more [27]. We give flow \( i \)'s credit to other flows in debt proportional to their weights, i.e., for each flow \( k \) such that \( l_{ag} < 0 \), we set

\[
l_{ag} = l_{ag} + l_{ag} \times \frac{r_k}{\sum_{m} l_{ag} < 0 r_m}.
\]

Then we reset \( l_{ag} = 0 \).

Below, we introduce the three schemes, Rate Selection Scheme, Graceful Degradation Scheme, and Compensation Scheme. Table 1 summarizes the notations used in MR-FQ.

2.3.1 Rate Selection Scheme

When a backlogged flow \( i \) is selected, the Rate Selection Scheme is invoked to choose a suitable transmission rate for flow \( i \) according to its lagging degree and channel condition. The basic idea is to permit different ranges of transmission rates according to flow \( i \)'s normalized lag, \( \frac{l_{ag}}{w_i} \). In order to help a seriously lagging flow to alleviate its huge lag, we allow it to use a larger range of rates. Specifically, we set up \( n - 1 \) levels of lagging thresholds \( \delta_1, \delta_2, \ldots, \delta_{n-1} \). A flow with a normalized lag exceeding \( \delta_i \) is allowed to use a rate as low as \( C_{i+1}, i \leq n - 1 \). Table 2 shows the mapping of lagging degrees to allowable transmission rates. If flow \( i \)'s current best rate falls within the allowable range, the rate is returned. Otherwise, a negative value is returned to indicate a failure. For example, if flow \( i \) satisfies \( \delta_2 < \frac{l_{ag}}{w_i} \leq \delta_1 \) and its current best rate is \( C_2 \), then \( C_2 \) is returned. If the current best rate is \( C_0 \), then a negative value is returned.
Flows are prioritized according to the following rules. First, lagging flows have a higher priority over non-lagging services. Flows are prioritized according to the following rules. Second, flows that can use lower rates. Third, among lagging flows of the same priority, lagging flows to receive such services. Flows are prioritized according to the following rules. First, lagging flows have a higher priority over non-lagging services. Flows are prioritized according to the following rules. Second, flows that can use lower rates. Third, among lagging flows of the same priority, lagging flows to receive such services. Flows are prioritized according to the following rules. First, lagging flows have a higher priority over non-lagging services. Flows are prioritized according to the following rules. Second, flows that can use lower rates. Third, among lagging flows of the same priority, lagging flows to receive such services.

2.3.2 Graceful Degradation Scheme

When a leading flow is selected for service, the Graceful Degradation Scheme is triggered to check its leading amount. A leading flow is allowed to receive an amount of additional service proportional to its normal services. Specifically, when a flow is transits from lagging/satisfied to leading, we set up a parameter $s_i = \alpha \cdot v_i$, where $\alpha (0 \leq \alpha \leq 1)$ is a system-defined constant. Later on, flow $i$‘s current virtual time is increased each time it is selected by the scheduler (according to earlier discussion, ‘selected’ does not mean that it is actually served). Let $v_i'$ be flow $i$'s current virtual time when it is selected. We allow flow $i$ to be served if $s_i \leq \alpha v_i'$. If so, $s_i$ is updated as $s_i + l_p / v_i$, where $l_p$ is the length of the packet. Intuitively, flow $i$ can enjoy approximately $\alpha(v_i' - v_i)$ services when it is leading.

Moreover, to distinguish RT from NRT flows, we substitute the above $\alpha$ by a parameter $\alpha_R$ for RT flows, and by $\alpha_N$ for NRT flows. We set $\alpha_R > \alpha_N$ to distinguish their priorities.

2.3.3 Compensation Scheme

When the selected flow does not have a satisfactory channel condition or fails to pass the Graceful Degradation Scheme, the Compensation Scheme is triggered (reflected by additional services in Fig. 3). Fig. 4 shows how to dispatch additional services. Flows are prioritized according to the following rules. First, lagging flows have a higher priority over non-lagging flows to receive such services. Second, flows that can use higher rates to transmit have a higher priority over flows that can use lower rates. Third, among lagging flows of the same rate, RT flows and NRT ones will share the services according to some ratio. Note that the third rule is not applied to leading flows because such flows suffer no lagging.

Next, we elaborate on the third rule. When dispatching additional services to lagging flows (i.e., flows on the left-hand side in Fig. 4), we keep track of the services received by RT ones and NRT ones. Let $L_R = L_R^1 \cup L_R^2 \cup \cdots \cup L_R^n$ be the set of RT, lagging flows, and $L_N = L_N^1 \cup L_N^2 \cup \cdots \cup L_N^n$ be the set of NRT, lagging flows. To let RT lagging flows receive more fraction of additional services without starving NRT lagging flows, we assign weights $W_R$ and $W_N$ (system parameters) to $L_R$ and $L_N$, respectively, to control the fractions of additional services they already received, where $W_R > W_N$. A virtual time $V_R$ (respectively, $V_N$) is used to record the normalized additional services received by $L_R$ (respectively, $L_N$). Flows in Fig. 4 are checked from left to right. When both $L_R^k$ and $L_N^k$ are non-empty, $1 \leq k \leq n$, the service is given to $L_R$ if $V_R < V_N$, and to $L_N$ otherwise. When only one of $L_R^k$ and $L_N^k$ is non-empty, the service is given to that one, independent of the values of $V_R$ and $V_N$. When a flow in $L_R$ receives the service, $V_R$ is updated as

$$V_R = \min \left\{ V_R + \frac{l_p}{W_R} , \frac{B + V_N W_N}{W_R} \right\},$$

(7)

where $l_p$ is the length of the packet being transmitted, and $B$ is a predefined value to bound the difference between $V_R$ and $V_N$. Similarly, when a flow in $L_N$ receives the service, $V_N$ is updated as

$$V_N = \min \left\{ V_N + \frac{l_p}{W_N} , \frac{B + V_R W_R}{W_N} \right\}.$$

(8)

Note that to avoid $V_R \gg V_N$ (respectively, $V_N \gg V_R$), which may cause flows in $L_R$ (respectively, $L_N$) to starve, we set up a bound $|V_R W_R - V_N W_N| \leq B$. This is reflected by the second term in the right-hand side of Eqs. (7) and (8).

When the scheduler selects either $L_R^k$ or $L_N^k$, it distributes additional services proportional to the weights of flows in that set. Specifically, for each flow $i$, we maintain a compensation virtual time $c_i$ to keep track of the normalized amount of
additional services received by flow $i$. The scheduler selects the flow $i$ with the smallest $c_i$ to serve, and then updates $c_i$ as

$$c_i = c_i + \left( \frac{L_p}{w_i} \times \frac{\hat{C}_i}{\hat{C}_k} \right) ,$$

(9)

Initially, when a flow $i$ newly enters $L_R$ or $L_N$, its $c_i$ is set to

$$c_i = \max\{c_i, \min\{c_j \mid \text{flow } j \text{ belongs to the same set of flow } i (L_R \text{ or } L_N), j \neq i \} \} .$$

If there is no lagging flow in the previous stage, the service is returned back to the originally selected flow if it is a leading flow but rejected by the Graceful Degradation Scheme. Otherwise, the service is given to a non-lagging flow that can use the highest rate. In case of a tie, MR-FQ dispatches the services proportional to some weights. Specifically, each flow $i$ is assigned with an extra virtual time $f_i$ to keep track of the normalized amount of additional services received by flow $i$ when it is non-lagging ($\mu_i \leq 0$). Whenever a backlogged flow $i$ that can send becomes non-lagging, $f_i$ is set to

$$f_i = \max\{f_i, \min\{f_j \mid \text{flow } j \text{ is backlogged, non-lagging and can send, } j \neq i \} \} .$$

The scheduler selects the flow $i$ with the smallest $f_i$ to serve. When flow $i$ receives the service, $f_i$ is updated as

$$f_i = f_i + \left( \frac{L_p}{w_i} \times \frac{\hat{C}_i}{\hat{r}} \right) ,$$

(10)

where $\hat{r}$ is the current best rate for flow $i$.

3 Fairness and Delay Analysis

In this section, we demonstrate that MR-FQ can guarantee fairness (including service fairness and time fairness) and bounded delays for packet flows by mathematical modeling and analyses. Our analyses rely on the following assumptions: 1) $\alpha_R > \alpha_N$, 2) $W_R > W_N$, 3) $B > \hat{L}_m$, and 4) $r_i \in \{\hat{C}_1, \cdots, \hat{C}_n\}$, where $\hat{L}_m$ is the maximum length of a packet and $r_i$ is the transmission rate used by flow $i$. A flow is called allowed-to-send if the Rate Selection Scheme returns a positive transmission rate to it, and is called a candidate if it can use a higher rate compared to other flows such that the scheduler may choose it to receive additional services in the Compensation Scheme. Besides, we let $r_{\text{min}}$ be the smallest transmission rate that flow $i$ has ever used during the nearest time interval when flow $i$ is active. The lemmas used in the proofs can refer to the appendix.

3.1 Service Fairness

Theorems 1 and 2 show the service fairness guaranteed by MR-FQ under some constraints. Theorem 1 is for flows that have the similar conditions and Theorem 2 provides some bounds on differences of services received by $L_R$ and $L_N$.

Theorem 1. For any two active flows $i$ and $j$, assume that both flows are continuously backlogged and allowed-to-send, and remain in the same state (leading, lagging, or satisfied) during a time interval $[t_1, t_2]$. Let $r_R$ and $r_C$ be the transmission rates used by these flows in the Rate Selection Scheme and the Compensation Scheme during $[t_1, t_2]$, respectively, where $r_R$ and $r_C$ are both in $\{\hat{C}_1, \cdots, \hat{C}_n\}$, and their values do not change during $[t_1, t_2]$. Then the difference between the normalized services received by flows $i$ and $j$ during $[t_1, t_2]$ satisfies the following inequality:

$$\left| \frac{\Phi_r^i(t_1, t_2)}{w_i} - \frac{\Phi_r^j(t_1, t_2)}{w_j} \right| \leq \beta \frac{\hat{L}_m}{w_i} + \gamma \frac{\hat{L}_m}{w_j} ,$$

where $\Phi_r^i(t_1, t_2)$ represents the services received by flow $i$ during $[t_1, t_2]$, and

$$\left( \beta, \gamma \right) = \left( \frac{r_R}{r_{\text{min}}} + 1, \frac{r_C + \alpha_R \hat{C}_1}{r_{\text{min}}r_R} \right) \left( \frac{r_C + \alpha_N \hat{C}_1}{r_{\text{min}}r_C} + 2 \right)$$

if both flows are lagging but not candidates,

$$\left( \beta, \gamma \right) = \left( \frac{r_R}{r_{\text{min}}} + 1, \frac{r_R + \alpha_N \hat{C}_1}{r_{\text{min}}r_R} + 1 \right)$$

if both flows are lagging and candidates,

$$\left( \beta, \gamma \right) = \left( \frac{r_C + \alpha_N \hat{C}_1}{r_{\text{min}}r_C} + 2, \frac{r_C + 2\alpha_N \hat{C}_1}{r_{\text{min}}r_C} + 2 \right)$$

if both flows are satisfied,

$$\left( \beta, \gamma \right) = \left( \frac{r_R}{r_{\text{min}}} + 2, \frac{r_R + 2\alpha_N \hat{C}_1}{r_{\text{min}}r_R} + 2 \right)$$

if flows $i$ and $j$ are both RT leading flows,

$$\left( \beta, \gamma \right) = \left( \frac{r_C}{r_{\text{min}}} + 2, \frac{r_C + 2\alpha_N \hat{C}_1}{r_{\text{min}}r_C} + 2 \right)$$

if flows $i$ and $j$ are both NRT leading flows, respectively.

Proof: A lagging flow that is allowed-to-send is not necessarily a candidate since there may exist other lagging flows that can use higher rates to transmit. Thus, we have to consider the five cases: 1) flows $i$ and $j$ are both lagging but not candidates, 2) flows $i$ and $j$ are both lagging and candidates, 3) flows $i$ and $j$ are both satisfied, 4) flows $i$ and $j$ are both leading and have the same traffic type, and 5) flows $i$ and $j$ are a RT leading flow and $j$ is a NRT leading flow during the entire time interval $[t_1, t_2]$.

Case (1): In this case, any flow $i$ that is lagging but not a candidate can only receive services each time when it is selected by $v_i$. Since $v_i$ is updated before a packet is transmitted, the services received by flow $i$ may deviate from its virtual time by one packet. Besides, the services received by flow $i$ is $v_i \times \frac{L_m}{\hat{C}_i}$. Thus, we have

$$\frac{r_R}{\hat{C}_1} (v_i(t_2) - v_i(t_1)) - \frac{\hat{L}_m}{w_i} \leq \frac{\Phi_r^i(t_1, t_2)}{w_i} \leq \frac{r_R}{\hat{C}_1} (v_i(t_2) - v_i(t_1)) + \frac{\hat{L}_m}{w_i} .$$

(11)

Applying Eq. (11) to flows $i$ and $j$, we have

$$\frac{r_R}{\hat{C}_1} (v_j(t_2) - v_j(t_1)) - \frac{\hat{L}_m}{w_j} \leq \frac{\Phi_r^j(t_1, t_2)}{w_j} \leq \frac{r_R}{\hat{C}_1} (v_j(t_2) - v_j(t_1)) + \frac{\hat{L}_m}{w_j} .$$

By Lemma 1, the leftmost term can be reduced to

$$\frac{r_R}{\hat{C}_1} (v_j(t_2) - v_j(t_2) - (v_i(t_1) - v_j(t_1))) \leq \frac{\frac{\hat{L}_m}{w_i}}{\frac{r_{\text{min}}}{w_j} + 1} .$$

Thus, we have

$$\frac{\hat{L}_m}{w_i} \leq \left( \frac{r_R}{r_{\text{min}}} + 1 \right) \frac{\hat{L}_m}{w_j} .$$

(12)
Similarly, the rightmost term would be less than or equal to
\[
\left( \frac{r_m}{r_m^\text{min}} + 1 \right) \frac{L_m}{w_i} + \left( \frac{r_n}{r_n^\text{min}} + 1 \right) \frac{L_m}{w_j},
\]
so
\[
\left| \Phi_i(t_1, t_2) - \Phi_j(t_1, t_2) \right| \leq \left( \frac{r_R}{r_R^\text{min}} + 1 \right) \frac{L_m}{w_i} + \left( \frac{r_R}{r_R^\text{min}} + 1 \right) \frac{L_m}{w_j}.
\]

Case (2): In this case, both flows can receive services each time when they are selected by \( v_i/v_j \), or receive additional services from others by \( c_i/c_j \). Since the additional services received by flow \( i \) are \( c_i \times \frac{C_1}{C_1} \), we have
\[
\frac{r_R}{C_1} (v_i(t_2) - v_i(t_1)) + \frac{r_C}{C_1} (c_i(t_2) - c_i(t_1)) - \frac{L_m}{w_i} \leq \Phi_i(t_1, t_2) \left( \frac{L_m}{w_i} \right)
\]
\[
\leq \frac{r_R}{C_1} (v_i(t_2) - v_i(t_1)) + \frac{r_C}{C_1} (c_i(t_2) - c_i(t_1)) + \frac{L_m}{w_i}.
\]

Similarly to case 1, by Lemmas 1 and 2, we can obtain
\[
\left| \Phi_i(t_1, t_2) - \Phi_j(t_1, t_2) \right| \leq \left( \frac{R + r_C}{r_C^\text{min}} + 1 \right) \frac{L_m}{w_i} + \left( \frac{R + r_C}{r_C^\text{min}} + 1 \right) \frac{L_m}{w_j}.
\]

Case (3): In this case, both flows can receive services each time when they are selected by \( v_i/v_j \), or when they receive additional services from another flow by \( f_i/f_j \). Besides, since the additional services received by flow \( i \) are \( f_i \times \frac{C_1}{C_1} \), we have
\[
\frac{r_R}{C_1} (v_i(t_2) - v_i(t_1)) + \frac{r_C}{C_1} (f_i(t_2) - f_i(t_1)) - \frac{L_m}{w_i} \leq \Phi_i(t_1, t_2) \left( \frac{L_m}{w_i} \right)
\]
\[
\leq \frac{r_R}{C_1} (v_i(t_2) - v_i(t_1)) + \frac{r_C}{C_1} (f_i(t_2) - f_i(t_1)) + \frac{L_m}{w_i}.
\]

Consequently, similar to case 1, by Lemmas 1 and 3, we can obtain
\[
\left| \Phi_i(t_1, t_2) - \Phi_j(t_1, t_2) \right| \leq \left( \frac{R + r_C}{r_C^\text{min}} + 1 \right) \frac{L_m}{w_i} + \left( \frac{R + r_C}{r_C^\text{min}} + 1 \right) \frac{L_m}{w_j}.
\]

Case (4): An allowed-to-send, backlogged, leading flow \( i \) can receive services by \( s_i \) and additional services from other flows by \( f_i \). So the total services received by flow \( i \) during \( [t_1, t_2] \) are bounded as
\[
s_i(t_2) - s_i(t_1) + \frac{r_C}{C_1} (f_i(t_2) - f_i(t_1)) - \frac{L_m}{w_i} \leq \Phi_i(t_1, t_2) \left( \frac{L_m}{w_i} \right)
\]
\[
\leq s_i(t_2) - s_i(t_1) + \frac{r_C}{C_1} (f_i(t_2) - f_i(t_1)) + \frac{L_m}{w_i}.
\]

Applying the previous inequality to flows \( i \) and \( j \), we have
\[
\frac{r_C}{C_1} (f_i(t_2) - f_i(t_1)) + \frac{r_C}{C_1} (f_j(t_2) - f_j(t_1)) + s_i(t_2) - s_j(t_2)
\]
\[
= s_i(t_1) + s_j(t_1) - \frac{L_m}{w_i} - \frac{L_m}{w_j}
\]
\[
\leq \Phi_i(t_1, t_2) - \Phi_j(t_1, t_2)
\]
\[
\leq \frac{r_C}{C_1} (f_i(t_2) - f_i(t_1)) + \frac{r_C}{C_1} (f_j(t_2) - f_j(t_1)) + s_i(t_2) - s_j(t_2)
\]
\[
- s_i(t_1) + s_j(t_1) + \frac{L_m}{w_i} + \frac{L_m}{w_j}.
\]

Applying Lemma 4 twice to flows \( i \) and \( j \) and subtracting one by the other, we have
\[
\alpha (v_i(t) - v_j(t)) + \alpha (\frac{L_m}{w_i} - \frac{L_m}{w_j}) - \frac{L_m}{w_i} \leq s_i(t) - s_j(t)
\]
\[
\leq \alpha (v_i(t) - v_j(t)) + \alpha (\frac{L_m}{w_i} - \frac{L_m}{w_j}) + \frac{L_m}{w_i}.
\]

By Lemma 1, we can rewrite the inequality as
\[
- \left( \frac{C_1}{r_i} - \alpha + 1 \right) \frac{L_m}{w_i} = \frac{L_m}{w_i}.
\]
\[
\leq s_i(t) - s_j(t) \leq \left( \frac{C_1}{r_i} - \alpha + 1 \right) \frac{L_m}{w_i} + \frac{L_m}{w_i}.
\]

Applying Eq. (13) and Lemma 3 to Eq. (12), we have
\[
\left| \Phi_i(t_1, t_2) - \Phi_j(t_1, t_2) \right| \leq \left( \frac{r_C + \alpha C_1}{r_C^\text{min}} + 2 \right) \frac{L_m}{w_i} + \left( \frac{r_C + \alpha C_1}{r_C^\text{min}} + 2 \right) \frac{L_m}{w_j},
\]
where \( \alpha = \alpha_R \) if these flows are RT, and \( \alpha = \alpha_N \) if they are NRT.

Case (5): Applying Lemma 4 to flows \( i \) and \( j \) and taking a subtraction leads to
\[
\alpha_R v_i(t) - \alpha_R \frac{L_m}{w_i} - \left( \alpha_N v_j(t) - (\alpha_N - 1) \frac{L_m}{w_j} \right)
\]
\[
\leq s_i(t) - s_j(t)
\]
\[
\leq \alpha_R v_i(t) - (\alpha_R - 1) \frac{L_m}{w_i} - \alpha_N v_j(t) - (\alpha_N - 1) \frac{L_m}{w_j}
\]
\[
= S_{\text{right}}.
\]

By Lemma 1 and the \( \alpha_R > \alpha_N \) principle, the left-hand side of Eq. (14) becomes
\[
\alpha_R v_i(t) - \alpha_N v_j(t) + \alpha_N \frac{L_m}{w_j} - \alpha_R \frac{L_m}{w_i} - \frac{L_m}{w_j}
\]
\[
> \alpha_N (v_i(t) - v_j(t)) + \alpha_N \frac{L_m}{w_j} - \alpha_R \frac{L_m}{w_i} - \frac{L_m}{w_j}
\]
\[
\geq - \alpha_R \frac{L_m}{w_i} - \left( \alpha_N \frac{C_1}{r_j^\text{min}} - \alpha_N + 1 \right) \frac{L_m}{w_j}.
\]
Consider the right-hand side of Eq. (14). There are two cases for the term \( \alpha_R v_i(t) - \alpha_N v_j(t) \). If \( \alpha_R v_i(t) - \alpha_N v_j(t) \geq 0 \), we have \( v_i(t) \geq \frac{\alpha}{\alpha_R} v_j(t) \). By Lemma 1,

\[
S_{right} \leq \alpha_N (v_j(t) - v_i(t)) + \alpha_R \tilde{L}_m \left( \frac{\alpha}{\alpha_R} \right) w_j + \alpha_R \tilde{L}_m \left( \frac{\alpha}{\alpha_R} \right) w_i
\]

If \( \alpha_R v_i(t) - \alpha_N v_j(t) < 0 \), we have

\[
S_{right} \leq \alpha_N \tilde{L}_m \left( \frac{\alpha}{\alpha_R} \right) w_j + (1 - \alpha_R) \tilde{L}_m \left( \frac{\alpha}{\alpha_R} \right) w_i
\]

These two cases together imply

\[
S_{right} \leq \left( \alpha_N \frac{C_1}{r_{j_{\min}}} + \alpha_N \right) \tilde{L}_m \left( \frac{\alpha}{\alpha_R} \right) w_j + (1 - \alpha_R) \tilde{L}_m \left( \frac{\alpha}{\alpha_R} \right) w_i.
\]

So we have

\[
- \alpha_R \tilde{L}_m \left( \frac{\alpha}{\alpha_R} \right) w_i - \left( \alpha_N \frac{C_1}{r_{j_{\min}}} - \alpha_N + 1 \right) \tilde{L}_m \left( \frac{\alpha}{\alpha_R} \right) w_j \leq s(t) - s_j(t)
\]

By applying Eq. (15) and Lemma 3 to Eq. (12), we have

\[
\left| \Phi_R^i(t_1, t_2) - \Phi_N^i(t_1, t_2) \right| \leq \left( \frac{r_C}{r_{i_{\min}}} + 2 \right) \tilde{L}_m \left( \frac{\alpha}{\alpha_R} \right) w_i
\]

**Theorem 2.** The difference between normalized additional services received by \( L_R \) and \( L_N \) in any time interval \([t_1, t_2]\) during which both sets remain active (i.e., there exists at least one candidate in each set) satisfies the following inequality:

\[
\left| \Phi_R^i(t_1, t_2) - \Phi_N^i(t_1, t_2) \right| \leq \frac{B + \tilde{L}_m}{w_i} + \frac{B + \tilde{L}_m}{w_j},
\]

where \( \Phi_R^i(t_1, t_2) \) and \( \Phi_N^i(t_1, t_2) \) are additional services received by \( L_R \) and \( L_N \) during \([t_1, t_2]\), respectively.

**Proof:** Since \( V_R \) is updated before a packet is transmitted, it follows that the total additional services received by \( L_R \) during \([t_1, t_2]\) are bounded by

\[
V_R(t_2) - V_R(t_1) - \frac{\tilde{L}_m}{w_R} \leq \frac{\Phi_R^i(t_1, t_2)}{w_R} \leq V_R(t_2) - V_R(t_1) + \frac{\tilde{L}_m}{w_R}
\]

Similarly, for \( V_N \), we have

\[
V_N(t_2) - V_N(t_1) - \frac{\tilde{L}_m}{w_N} \leq \frac{\Phi_N^i(t_1, t_2)}{w_N} \leq V_N(t_2) - V_N(t_1) + \frac{\tilde{L}_m}{w_N}
\]

Therefore, we have

\[
V_R(t_2) - V_R(t_1) - \frac{\tilde{L}_m}{w_R} - \left( V_N(t_2) - V_N(t_1) + \frac{\tilde{L}_m}{w_N} \right)
\]

\[
\leq \frac{\Phi_R^i(t_1, t_2)}{w_R} - \frac{\Phi_N^i(t_1, t_2)}{w_N} \leq V_R(t_2) - V_R(t_1) + \frac{\tilde{L}_m}{w_R} - \left( V_N(t_2) - V_N(t_1) + \frac{\tilde{L}_m}{w_N} \right).
\]

By Lemma 5, we can rewrite the inequality as

\[
- \left( \frac{B + \tilde{L}_m}{w_R} + \frac{B + \tilde{L}_m}{w_N} \right) \leq \frac{\Phi_R(t_1, t_2)}{w_R} - \frac{\Phi_N(t_1, t_2)}{w_N} \leq \frac{B + \tilde{L}_m}{w_R} + \frac{B + \tilde{L}_m}{w_N}.
\]

\[
\Rightarrow \left| \Phi_R^i(t_1, t_2) - \Phi_N^i(t_1, t_2) \right| \leq \frac{B + \tilde{L}_m}{w_R} + \frac{B + \tilde{L}_m}{w_N}.
\]

\[
\square
\]

**3.2 Time Fairness**

Theorem 3 shows the time fairness guaranteed by MR-FQ. Since \( v_i, c_i, \) and \( f_i \) reflect the transmission time used by flow \( i \), the proof of Theorem 3 is similar to that of Theorem 1, except that we do not multiply \( v_i, c_i, \) and \( f_i \), by \( \frac{w_n}{C_n} \) or \( \frac{w_F}{C_F} \) factors. Thus, we omit the proof of Theorem 3.

**Theorem 3.** For any two active flows \( i \) and \( j \), the difference between the normalized transmission time used by flows \( i \) and \( j \) in any time interval \([t_1, t_2]\) during which both flows are continuously backlogged and allowed-to-send, and remain in the same state (leading, lagging, or satisfied) satisfies the following inequality:

\[
\left| \Phi^i_f(t_1, t_2) - \Phi^j_f(t_1, t_2) \right| \leq \beta \frac{\tilde{L}_m}{w_i} + \gamma \frac{\tilde{L}_m}{w_j},
\]

where \( \Phi^i_f(t_1, t_2) \) represents the transmission time used by flow \( i \) during \([t_1, t_2]\), and

\[
(\beta, \gamma) = \left( \frac{C_1}{r_{i_{\min}}} + 1, \frac{C_1}{r_{j_{\min}}} + 1 \right)
\]

if both flows are lagging but not candidates,

\[
(\beta, \gamma) = \left( \frac{C_1}{r_{i_{\min}}} + 1, \frac{C_1}{r_{j_{\min}}} + 1 \right)
\]

if both flows are lagging and candidates,

\[
(\beta, \gamma) = \left( \frac{C_1}{r_{i_{\min}}} + 1, \frac{C_1}{r_{j_{\min}}} + 1 \right)
\]

if both flows are satisfied,

\[
(\beta, \gamma) = \left( \frac{(\alpha+1)C_1}{r_{i_{\min}}} + 2, \frac{(\alpha+1)C_1}{r_{j_{\min}}} + 2 \right)
\]

if both flows are RT leading flows,

\[
(\beta, \gamma) = \left( \frac{(\alpha+1)C_1}{r_{i_{\min}}} + 2, \frac{(\alpha+1)C_1}{r_{j_{\min}}} + 2 \right)
\]

if both flows are NRT leading flows,

\[
(\beta, \gamma) = \left( \frac{C_1}{r_{i_{\min}}} + 2, \frac{(\alpha+1)C_1}{r_{j_{\min}}} + 2 \right)
\]

if flows \( i \) and \( j \) are RT and NRT leading flows, respectively.

**3.3 Delay Bounds**

Theorem 4 shows that if a lagging flow which has sufficient service demand becomes allowed-to-send and is always a candidate in the Compensation Scheme, it can get back all its lagging services within bounded time.

**Theorem 4.** If an active but lagging flow \( i \) which remains backlogged continuously becomes allowed-to-send and is always a candidate in the Compensation Scheme, it is guaranteed that flow \( i \) will become non-lagging (i.e., \( lag_i \leq 0 \)) within time \( \Delta_t \), where

\[
\Delta_t < \frac{\varphi(\psi + 2\tilde{L}_m)^w}{w_{min}(1 - \alpha_R)\tilde{C}_n} + \left( \frac{\tilde{C}_1}{\tilde{C}_n} \frac{\psi}{(m + \varphi) + 1} \right) \frac{\tilde{L}_m}{\tilde{C}_n},
\]

\( m \) is the number of active flows, \( \varphi, \psi_R, \) and \( \varphi_N \) are the aggregate weight of all flows, all RT flows, and all NRT
flows, respectively; \( \omega_{\text{min}} \) is the minimum weight of all flows; and

\[
\psi = \frac{W_{\text{RT}}}{W_{\text{RT}}} \left( \sum_{n=l}^{\infty} \frac{\omega_{n \cdot \text{lag}}(t)}{w_i} + (2 \omega_{i \cdot \text{lag}}(t) + m - 2) \hat{L}_m \right) + 2 \hat{L}_m + B
\]

if flow \( i \) is RT,

\[
\hat{L}_m = \omega_{\text{min}}(1 - \alpha_R) (v_k(t + \Delta_t) - v_k(t)) - 2 \hat{L}_m \]

By combining Eqs. (17) and (18) into Eq. (16), we can obtain

\[
\Phi_A(t, t + \Delta_t) \geq \omega_{\text{min}} \cdot \frac{\hat{C}_1}{C_1} (v_k(t + \Delta_t) - v_k(t)) - \omega_{\text{min}}(s_k(t + \Delta_t) - s_k(t)) - \hat{L}_m. \tag{16}
\]

Not that the best rate of flow \( k \) must be \( \hat{C}_1 \), or it is not allowed to send. By Lemma 1, for any active flow \( j \) during \([t, t + \Delta_t]\), we have

\[
v_j(t + \Delta_t) - v_j(t) \leq v_k(t + \Delta_t) - v_k(t) + \frac{\hat{C}_1}{C_1} \left( \frac{\hat{L}_m}{w_j} + \frac{\hat{L}_m}{\omega_{\text{min}}} \right)
\]

This inequality helps to derive the total amount of services provided by the system during \([t, t + \Delta_t]\):

\[
\hat{C}_n \cdot \Delta_t \leq \left( \sum_{j \in A} w_j \cdot \frac{\hat{C}_1}{C_1} (v_j(t + \Delta_t) - v_j(t)) \right) + \hat{L}_m
\]

\[
\leq \left( \sum_{j \in A} w_j (v_k(t + \Delta_t) - v_k(t)) + \frac{\hat{C}_1}{C_1} \left( \frac{\hat{L}_m}{w_j} + \frac{\hat{L}_m}{\omega_{\text{min}}} \right) \right) + \hat{L}_m
\]

\[
\leq (v_k(t + \Delta_t) - v_k(t)) \sum_{j \in A} w_j + \frac{\hat{C}_1}{C_1} \left( m \hat{L}_m + \frac{\hat{L}_m}{\omega_{\text{min}}} \sum_{j \in A} w_j \right) + \hat{L}_m
\]

\[
\leq (v_k(t + \Delta_t) - v_k(t)) \varphi \left( \frac{\hat{C}_1}{C_1} (m + \frac{\varphi}{\omega_{\text{min}}}) + 1 \right) \hat{L}_m
\]

\[
\Rightarrow v_k(t + \Delta_t) - v_k(t) \geq \frac{1}{\varphi} \left( \hat{C}_n \cdot \Delta_t - \left( \frac{\hat{C}_1}{C_1} (m + \frac{\varphi}{\omega_{\text{min}}}) + 1 \right) \hat{L}_m \right). \tag{17}
\]

Applying Lemma 4 to flow \( k \) at times \( t \) and \( t + \Delta_t \) and taking a subtraction, we obtain

\[
s_k(t + \Delta_t) - s_k(t) \leq \alpha_R v_k(t + \Delta_t) - \alpha_R v_k(t) + \frac{\hat{L}_m}{\omega_{\text{min}}}. \tag{18}
\]
By combining Eqs. (21) and (22) into Eq. (20), we have
\[
\Phi_A(t, t + \Delta t) < \frac{W_R + W_N}{W_R} \left( \frac{C_1}{C_n} \frac{\varphi_R \cdot \text{lag}(t)}{w_i} \right) + \left( \frac{2 \varphi_R}{w_i} + m - 2 \right) \hat{z}_{m} + 2 \hat{z}_{n} + B. \quad (23)
\]
By combining Eqs. (19) and (23), the first part of this theorem is proved. When flow \( i \) is an NRT flow, the proof is similar and we omit the details.

4 Simulation Results

In this section, we present some experimental results to verify the effectiveness and properties of the proposed algorithm. We have developed an event-driven simulator by using C++ programming language. Events, such as packets’ arrival and change of channel states, are tagged with timestamps and enqueued into a priority queue. The simulator then dequeues events from the priority queue and handles them by the principles of MR-FQ.

4.1 The Impact of Multi-Rate Environment

In the first experiment, we evaluate the impact of the multi-rate environment for our MR-FQ method and other wireless fair scheduling algorithms. We mix RT and NRT flows together. We mainly observe the packet dropping ratios and the average queuing delays of RT flows and the average throughput of NRT flows. We compare CIF-Q [10], TD-FQ [13], and the proposed MR-FQ. CIF-Q and TD-FQ are two wireless fair scheduling algorithms developed for a single-rate environment. They both assume that the wireless channel is either in a good state or a bad state. We compare MR-FQ with these two algorithms because their basic scheduling policies (i.e., Fig. 3) are similar to that of MR-FQ. (The major differences among these three scheduling algorithms are the methods of Graceful Degradation Scheme and Compensation Scheme. Besides, only MR-FQ has the Rate Selection Scheme.) We adopt the IEEE 802.11b as the MAC protocol, which provides 11 Mb/s, 5.5 Mb/s, 2 Mb/s, and 1 Mb/s transmission rates. Ten flows are used, as shown in Table 3. The first six flows are RT flows, which represent three traffic models: video, voice, and constant-bit-rate (CBR) traffics. The voice traffic is modeled as an ON-OFF process, where the average durations of ON and OFF periods are set to 2.5 and 0.5 seconds, respectively. During an ON period, packets are generated with fixed intervals. No packet is generated during an OFF period. The video traffic is modeled as variable-bit-rate (VBR) traffic, where packets arrive in a Poisson fashion. The last four flows are NRT FTP flows, and their traffic is modeled as greedy sources whose queues are never empty. The weights of these flows are set to 2 : 1 : 64 : 32 : 16 : 8 : 64 : 64 : 64 : 64 to reflect their guaranteed bandwidth. As for error scenarios, we use two parameters \( T_{\text{good}} \) and \( T_{\text{bad}} \) to adjust the average time when a channel stays in good and bad states, respectively. When the channel is in the good state, the best transmission rate that a flow can use in a bad state, the best transmission rate that a flow can use is randomly selected from 5.5, 2, 1, and 0 Mb/s. However, both CIF-Q and TD-FQ simply treat the channel as bad and no packet can be transmitted. The total simulation time in this experiment is 30 minutes.

For CIF-Q, we set its parameter \( \alpha = 0.5 \), while for TD-FQ and MR-FQ, we set their parameters \( \alpha_R = 0.8 \) and \( \alpha_N = 0.2 \), respectively. In TD-FQ, the weights assigned to lagging sets are \( W_R : W_N = 3 : 1, W_R : W_N = 3 : 1 \), and \( W_R : W_N = 3 : 1 \). In MR-FQ, since we do not distinguish lagging flows as seriously and moderately lagging ones, there is only one ratio \( W_R : W_N = 3 : 1 \). Besides, the values of \( \delta_1, \delta_2, \delta_3, \) and \( B \) in MR-FQ are set to 32, 64, 128, and 1024, respectively. Note that the units of packets are set to Kb when we compute the virtual time of flows.

The packet dropping ratios and the average queuing delays of RT flows are shown in Figs. 5 and 6, respectively, where the packet dropping ratio is defined as the ratio of the number of packets dropped due to exceeding deadline to the number of packet generated, and the deadline of a packet is set to twice of the average packet inter-arrival time. From Figs. 5 and 6, we can observe that RT flows have the highest packet dropping ratios and average queuing delays when we apply CIF-Q to the scheduler. This is because CIF-Q does not separate RT flows from NRT flows and treat all flows in the same way. RT flows then have to compete with NRT flows, thus causing higher dropping ratios and queuing delays. The packet dropping ratios and the average queuing delays of RT flows in TD-FQ are smaller than those in CIF-Q. This is because TD-FQ gives higher priorities to RT flows to reduce their queuing delays (and packet dropping ratios). MR-FQ adopts the idea of TD-FQ (that gives higher priorities to RT flows) and allows flows in a bad state to transmit packets using lower rates (if possible). So the packet dropping ratios and the average queuing delays of RT flows in MR-FQ are smaller than those in CIF-Q and TD-FQ since the latter two methods do not allow packets to be transmitted if flows are in a bad state.

![Fig. 5: Packet dropping ratios of RT flows.](image)

A similar effect can be observed in Fig. 7, where the average throughput of NRT flows in MR-FQ are larger than that in CIF-Q and TD-FQ.

From this experiment, we can conclude that by considering...
multi-rate capability of a wireless channel, the proposed MR-FQ method can reduce the packet dropping ratios and average queuing delays of RT flows and increase the overall system performance.

4.2 The Time Fairness Property

In the second experiment, we verify the time fairness property of the MR-FQ method. Recall that there are two parts in MR-FQ that address the time fairness issue. One is the Rate Selection Scheme, which will choose a suitable transmission rate for the selected flow according to its lagging degree and channel condition. A flow is allowed to use a lower rate for transmission only if it is suffering from seriously lagging. Another is the ratio $\hat{c}_i$ used to update a flow’s virtual time (refer to Eqs. (3), (9), and (10)), where $r$ is the transmission rate used by the flow. To show that our MR-FQ method can satisfy the time fairness property, we design a modified version of MR-FQ that does not consider the time fairness property. This modified version removes the Rate Selection Scheme and updates a flow $i$’s virtual time as $v_i = v_i + l_p w_i$, $c_i = c_i + l_p w_i$, and $f_i = f_i + l_p w_i$, where $l_p$ is the length of the packet being transmitted. We mainly observe the total services received by flows and the total medium time used by flows. Two FTP flows are used, as shown in Table 4. The weights of these two FTP flows are set to 1 : 1. The total simulation time in this experiment is 100 seconds.

Figs. 8 and 9 show the total services received and the total medium time used by both flows. Two FTP flows are used, as shown in Table 4. The weights of these two FTP flows are set to 1 : 1. The total simulation time in this experiment is 100 seconds.

Services received by FTP flows (a) MR-FQ. (b) MR-FQ without considering time fairness.

{Fig. 8: Total services received by the FTP flows. (a) MR-FQ. (b) MR-FQ without considering time fairness.}

Services transmitted by FTP flows (a) MR-FQ. (b) MR-FQ without considering time fairness.

(Note that since the flow FTP2 has a worse channel condition,
it will often use lower transmission rates to send packets, thus causing longer transmission time.) By comparing Fig. 8 (a) and (b), we can observe that the total services received by the flow FTP1 in the modified version of MR-FQ are quite lower than that in MR-FQ. This reflects the fact that if we do not consider the time fairness issue, the flows using lower transmission rates will degrade the amount of services received by other flows (that use higher transmission rates), and thus decreasing the overall system performance.

To show how bad the situation will be if we ignore the time fairness issue, we set up the third experiment. Six flows are used, as shown in Table 5. We mainly observe the services received by each flow and the total services provided by the system. The weights of these six flows are set to $1 : 8 : 32 : 64$ to reflect their guaranteed bandwidth. The total simulation time in this experiment is 30 minutes. We mainly observe the services received by each flow and the total services provided by the system.

4.3 The Effect of $\alpha_R$ Value on RT Leading Flows

In the last experiment, we discuss the effect of different $\alpha_R$ values on RT leading flows in our MR-FQ method. Recall that with the Graceful Degradation Scheme, a RT leading flow $i$ can reserve approximately $\alpha_R v_i$ services. (In other words, flow $i$ has to give up approximately $(1-\alpha_R) v_i$ services to compensate other lagging flows.) These reserved services can help reduce the queueing delays of RT leading flows.

To evaluate the effect of different $\alpha_R$ values, we set up four flows, as shown in Table 6. The first three flows are RT flows, which represent three traffic models: voice, CBR, and video traffics. The last flow is a NRT FTP flow. The channel conditions of these three RT flows are much better than that of the NRT FTP flow. So these RT flows will become leading flows while the NRT FTP flow will become a lagging flow in this experiment. Note that the major purpose of this NRT FTP flow is to receive compensation services from these three RT flows so that we can observe the effect of different $\alpha_R$ values on these RT flows. The weights of these four flows are set to $1 : 8 : 32 : 64$ to reflect their guaranteed bandwidth. The total simulation time in this experiment is 30 minutes. We mainly observe the packet dropping ratios (which also reflect the queueing delays) of RT flows in this experiment.

![Fig. 11: Total services provided by the system.](image)

---

Fig. 12 shows the packet dropping ratios of these three RT leading flows under different $\alpha_R$ values. The packet dropping ratios of RT flows decrease broadly as the value of $\alpha_R$ increases. From Fig. 12, we can observe that the $\alpha_R$ value does not obviously affect the packet dropping ratio of the voice flow when $\alpha_R > 0.2$. This is because the voice traffic is modeled as an ON-OFF process, and packets are generated only during an ON period. So even we give more services to the voice flow, its queue may be empty and cannot receive such services. The packet dropping ratio of the CBR flow decreases as the value of $\alpha_R$ increases when $\alpha_R \leq 0.3$. This is because the packet’s arrival rate is fixed in the CBR flow. When we set $\alpha_R = 0.3$ in this experiment, the CBR flow can exactly exhaust its queue.
content. So when $\alpha_R > 0.3$, the queue becomes empty and the packet dropping ratio of the CBR flow becomes steady. The value of $\alpha_R$ affects the packet dropping ratio of the video flow obviously when $\alpha_R \leq 0.6$. This is because the video flow is modeled as VBR traffic, where packets arrive in a Poisson fashion, and thus its queue may contain more packets waiting for transmission.

Proof: This proof is by induction on $t$.

**Basic step.** When $t = 0$, all virtual times are 0, so Eq. (24) holds trivially.

**Induction step.** Suppose that at time $t$, Eq. (24) holds. Let $t + \Delta_i$ be the nearest time when any flow changes its virtual time. We want to prove Eq. (24) for time $t + \Delta_i$. Observe that a flow’s virtual time may be updated in three cases: 1) it is selected by the scheduler and the service is indeed given to it, 2) it is selected by the scheduler but the service is given to another flow, and 3) it becomes active.

In case 1), let flow $i$ be selected by the scheduler and use transmission rate $r_i \geq r_{i}^{\text{min}}$ to send. Then its virtual time becomes $v_i(t + \Delta_i) = v_i(t) + \left( \frac{l_p \times \hat{C}_1}{r_i} \right)$, where $l_p$ is the length of the packet being transmitted. By MR-FQ, it follows that $v_i(t + \Delta_i) \leq v_j(t)$, for all $j \in A$. Since $v_i$ is increased, by the induction hypothesis, we have

$$\frac{L_m}{w_j} \times \frac{\hat{C}_1}{r_j^{\text{min}}} \leq v_i(t + \Delta_i) - v_j(t) = v_i(t + \Delta_i) - v_j(t + \Delta_i).$$

Further, since $v_i(t + \Delta_i) \leq v_j(t)$, we have

$$v_i(t + \Delta_i) - v_j(t) = \left( v_i(t) + \frac{l_p \times \hat{C}_1}{r_j} \right) - v_j(t).$$

So Eq. (24) holds at $t + \Delta_i$.

In Eq. (24), if flow $j$ is selected by the scheduler and it uses transmission rate $r_j \geq r_j^{\text{min}}$ to send, then $v_i(t + \Delta_i) - v_j(t + \Delta_i) \leq \frac{L_m}{w_j} \times \frac{\hat{C}_1}{r_j^{\text{min}}}$ holds trivially. Further,

$$v_i(t + \Delta_i) - v_j(t + \Delta_i) = v_i(t) - \left( v_j(t + \Delta_i) \right) \geq \frac{L_m}{w_j} \times \frac{\hat{C}_1}{r_j^{\text{min}}}.$$ 

So Eq. (24) still holds at $t + \Delta_i$.

Case 2) is similar to case 1), except that we need to replace $r_i$ and $r_j$ by $\hat{C}_1$ in all inequalities.

In case 3), suppose that flow $i$ becomes active at $t + \Delta_i$. By MR-FQ, $v_i(t + \Delta_i)$ is set to max $\{v_i(t), \min_{k \in A - \{i\}} \{v_k(t + \Delta_i)\}\}$. If $v_i(t + \Delta_i) = \min_{k \in A - \{i\}} \{v_k(t + \Delta_i)\}$, then Eq. (24) holds trivially. Otherwise, $v_i(t + \Delta_i) = v_i(t)$, which means that $v_i(t) \geq \min_{k \in A - \{i\}} \{v_k(t + \Delta_i)\}$. So we have

$$v_i(t + \Delta_i) - v_j(t + \Delta_i) \geq \min_{k \in A - \{i\}} \{v_k(t + \Delta_i)\} - v_j(t + \Delta_i).$$

Since the virtual time is non-decreasing, we have

$$v_i(t + \Delta_i) - v_j(t + \Delta_i) \leq v_i(t) - v_j(t) \leq \frac{L_m}{w_i} \times \frac{\hat{C}_1}{r_i^{\text{min}}}.$$ 

So Eq. (24) holds at $t + \Delta_i$. When flow $j$ becomes active, the proof is similar, so we can conclude the proof.

Since MR-FQ updates $c_i$ and $r_i$ similarly to that of $v_i$, proofs of the next two lemmas are similar to that of Lemma 1. So we omit the proofs.

**Lemma 2.** Let $c_i(t)$ be the compensation virtual time of flow $i$ at time $t$. For any two flows $i$ and $j$ which are both candidates
and have the same traffic type (RT or NRT) such that \( t \geq 0 \), we have
\[
-\frac{L_m}{w_i} \times \frac{C_i}{v_i^\text{min}} \leq c_i(t) - c_j(t) \leq \frac{L_m}{w_i} \times \frac{C_j}{v_j^\text{min}}.
\]

**Lemma 3.** Let \( f_i(t) \) be the extra virtual time of flow \( i \) at time \( t \).
For any two flows \( i \) and \( j \) that are both candidates such that \( t \geq 0 \), we have
\[
-\frac{L_m}{w_i} \times \frac{C_i}{v_i^\text{min}} \leq f_i(t) - f_j(t) \leq \frac{L_m}{w_i} \times \frac{C_j}{v_j^\text{min}}.
\]

The next lemma gives bounds on the difference between the normalized services received by a leading flow \( i \) (i.e., \( s_i \)) and the maximum amount that it can receive (i.e., \( \alpha_i v_i \)).

**Lemma 4.** Let \( s_i(t) \) be the value of \( s_i \) at time \( t \). For any flow \( i \) that is allowed-to-send, backlogged, and leading during the time interval \( t \in [t_1, t_2] \), we have
\[
(\alpha - 1) \frac{L_m}{w_i} \leq \alpha v_i(t) - s_i(t) \leq \alpha \frac{L_m}{w_i},
\]
where \( \alpha = \alpha_\text{R} \) if flow \( i \) is a RT flow, and \( \alpha = \alpha_\text{N} \) otherwise.

**Proof:** The proof is by induction on time \( t \in [t_1, t_2] \).

**Basic step.** When \( t = t_1 \), flow \( i \) just becomes leading, so the Graceful Degradation Scheme sets \( s_i(t) = \alpha v_i(t) \) and the lemma is trivially true.

**Induction step.** Suppose that at time \( t \), the lemma holds. Observe that \( v_i \) and/or \( s_i \) change only when flow \( i \) is selected. So we consider two cases: 1) flow \( i \) is actually served, and 2) another flow \( j \neq i \) is served. Let \( t + \Delta t \leq t_2 \) be the nearest time that \( v_i \) and/or \( s_i \) are updated. We prove that the lemma still holds at \( t + \Delta t \).

According to MR-FQ, case 1) occurs only when \( \Delta t_s(t) \leq \alpha v_i(t) \), so we have
\[
\alpha v_i(t + \Delta_t) - s_i(t + \Delta t) = \alpha (v_i(t) + \frac{L_p}{w_i}) - (s_i(t) + \frac{L_p}{w_i}) = (\alpha - 1) \frac{L_m}{w_i} + \alpha v_i(t) - s_i(t) \geq (\alpha - 1) \frac{L_m}{w_i},
\]
where \( L_p \) represents the length of the packet being transmitted.

Case 2) implies \( s_i(t) > \alpha v_i(t) \). Also, \( v_i \) is updated but \( s_i \) is not. So we have
\[
\alpha v_i(t + \Delta_t) - s_i(t + \Delta t) = \alpha (v_i(t) + \frac{L_p}{w_i}) - s_i(t) < \frac{L_p}{w_i} \leq \frac{L_m}{w_i}.
\]

**Lemma 5.** Let \( V_R(t) \) and \( V_N(t) \) be the value of \( V_R \) and \( V_N \), respectively. For \( t \geq 0 \), we have
\[
-\frac{B}{W_N} \leq V_R(t) - V_N(t) \leq \frac{B}{W_R}.
\]

**Proof:** This proof is by induction on time \( t \geq 0 \).

**Basic step.** When \( t = 0 \), \( V_R(t) = V_N(t) = 0 \), so the lemma is trivially true.

**Induction step.** Assume that the lemma holds at time \( t \). \( V_R \) (respectively, \( V_N \)) can be updated only when \( L_R^k \) (respectively, \( L_N^k \)) is non-empty, where \( L_R^k \) is the subset of \( L_R \) selected in the Compensation Scheme, respectively. We consider two cases: 1) only one set is non-empty, and 2) two sets are non-empty. Let \( t + \Delta_t \); be the nearest time that \( V_R \) or \( V_N \) is updated. We want to prove the lemma to be true at time \( t + \Delta_t \).

In case 1), if \( L_R^k \) is non-empty, additional services are given to \( L_R \). In MR-FQ, we bound the total difference of additional services received by \( L_R \) and \( L_N \) at any time by \( |W_R V_R(t + \Delta_t) - W_N V_N(t + \Delta_t)| \leq B \). So at time \( t + \Delta_t \), we have
\[
W_R V_R(t + \Delta_t) - W_R V_N(t + \Delta_t) \leq B
\]
On the other hand, if \( L_N^k \) is non-empty, we can similarly derive that \( V_R(t + \Delta_t) - V_N(t + \Delta_t) \geq -\frac{B}{W_N} \). So the lemma holds at \( t + \Delta_t \).

In case 2), since both sets are non-empty, the scheduler gives additional services to \( L_R \) if \( V_R(t) \leq V_N(t) \). Let \( l_p \) represents the length of the packet being transmitted. We have
\[
V_R(t + \Delta_t) - V_N(t + \Delta_t) \leq \left( V_R(t) + \frac{L_p}{W_R} \right) - \frac{L_m}{W_R} \leq \frac{B}{W_R}
\]
Note that it is trivially true that \( -\frac{B}{W_N} \leq V_R(t + \Delta_t) - V_N(t + \Delta_t) \). Similarly, if \( V_R(t) > V_N(t) \), the service is given to \( L_N \), so we have
\[
V_R(t + \Delta_t) - V_N(t + \Delta_t) = V_R(t) - \left( V_N(t) + \frac{L_p}{W_N} \right) \geq -\frac{L_m}{W_N} \geq -\frac{B}{W_N}.
\]

Note that it is trivially true that \( V_R(t + \Delta_t) - V_N(t + \Delta_t) \leq \frac{B}{W_N} \). Therefore, the lemma still holds at \( t + \Delta_t \).
